(Received 4 March 2011; accepted 1 July 2011; published online 4 August 2011)

The angular properties of light emitted from rare-earth based nanophosphors embedded in optical resonators built in one-dimensional photonic crystal coatings are herein investigated. Strong directional dependence of the photoluminescence spectra is found. Abrupt angular variations of the enhancement caused by the photonic structure and the extraction power are observed, in good agreement with calculated polar emission patterns. Our results confirm that the optical cavity favors the extraction of different wavelengths at different angles and that integration of nanophosphors within photonic crystals provides control over the directional emission properties that could be put into practice in phosphorescent displays. © 2011 American Institute of Physics. [doi:10.1063/1.3619814]

In recent years, multiple applications for rare-earth based nanoparticles, usually known as nanophosphors, have been developed in several fields like light emitting diodes (LEDs),1 sensors,2 and displays.3 In the latter case, all previous reports on the directional emission of nanophosphors within photonic crystals, which might be of relevance for their potential application in displays. Samples were prepared following a procedure reported elsewhere.10 Briefly, the optical resonator was built by sandwiching a layer of Eu-doped yttrium fluoride nanophosphors15 between two 1DPC consisting in alternated layers of SiO2 and TiO2 nanoparticles.16 The nanophosphor layer was surrounded by two SiO2 nanoparticle multilayers that disrupted the periodicity of the whole ensemble, leading to the opening of resonant modes. The nanophosphors employed emit photoluminescent bands in the visible range whose width Δλm is narrower than that of the cavity resonance, Δk (ΔλC/Δλm ≃ 6). Following a spin coating protocol,17 the resonator can be devised to present the resonance at the desired spectral position. The reference is prepared by sandwiching, between two layers of SiO2 particles, a layer of nanophosphors of the exact same thickness than that deposited to build the resonators.

In order to realize the measurements required for our work, the set up presented in Fig. 1 was disposed. A green solid-state laser emitting at λ = 532 nm is used as a continuous wave excitation source. A 30 mW beam is normally incident to the sample surface, focused down by means of a 10 cm-focal length lens. The light coming out of the multilayer structure in transmission mode is collected by an objective with a numerical aperture N.A. = 0.6, coupled into a multimode fiber, and spectrally dispersed by a monochromator.

In this work, we study experimentally the variation of the intensity of the photoluminescence bands of optical resonators containing nanophosphors as the angle of collection is changed. We observe a strong angular dependence of the spectrally selective enhancement achieved with respect to reference samples, which is in turn largely affected by the values of the optical parameters of the resonator. Our experimental data are analyzed on the basis of a simple theoretical model proposed by Benisty et al.,14 a qualitative agreement being found for the directional properties of both the extracted intensity and the enhancement of selected emission lines.

attached to a charge-coupled device (CCD) detector camera. An iris is placed between the objective and the detector to study the relation between the intensity of the emission bands and the light cones of angular widths comprised between 5.7° and 36.8°. The collection angle $\theta$ is determined through the radio $R$ of the iris according to $\tan(\theta) = R/f$, where $f$ is the focal of the objective ($f = 5$ mm). Modes that can be extracted from the structure are those whose internal emission angle $\alpha$, $\alpha = \sin^{-1}(\sin(\theta) n_{\text{air}}/n_{\text{res}})$, is smaller than the critical angle $\alpha_c \sim 52^2$; above $\alpha_c$, modes remain guided, i.e., they do not radiate to air. On the other hand, modes can be detected provided the collection angle matches the N.A. of the objective, $\theta < 37^\circ$. The transmittance spectra were obtained using the same set up but using a white supercontinuum laser that allows us to measure optical spectra between 400 nm and 800 nm.

Transmittance and photo-emission spectra corresponding to resonators with different cavity modes, namely $\lambda_c = 708$ nm and $\lambda_c = 742$ nm, are plotted in Fig. 2 (left and right panels, respectively). The transmittance spectra (light lines) as well as the luminescent emission spectrum of the reference (dark lines) are shown in Figs. 2(a) and 2(e). Their photoluminescence spectra collected at different angles are plotted in sets of graphs b, c, d and f, g, h, respectively. Vertical dashed lines indicate the position of the emission bands of the nanophosphors.

In Fig. 3, we plot the experimentally observed evolution of the intensities of the emission bands affected by the cavity resonances versus collection angle for the two resonators considered, with $\lambda_c = 708$ nm (Fig. 3(a)) and $\lambda_c = 742$ nm (Fig. 3(b)). The intensities of all the emission bands were divided by the maximum value measured for the band at $\lambda_c = 708$ nm for the sake of clarity and to facilitate the comparison with the theoretical results. In the first case, the normalized intensities of bands placed at $\lambda_B = 708$ nm (dark circles) and $\lambda_B = 655$ nm (light lobes) as a function of the collection angle.

An analysis of these angular trends was performed by comparing them to the emission of a dipole placed in the

**FIG. 2.** (Color online) Transmittance (light lines) and photoluminescence (dark lines) spectra of optical resonators whose cavity modes are centered at $\lambda_c = 708$ nm (a) and at $\lambda_c = 742$ nm (e). Their photoluminescence spectra collected at different angles are plotted in sets of graphs b, c, d and f, g, h, respectively. Vertical dashed lines indicate the position of the emission bands of the nanophosphors.

**FIG. 3.** (Color online) (a) Extraction power in an escape cone of angle $\theta$ of emission bands centered at $\lambda_B = 708$ nm and $\lambda_B = 655$ nm measured from the resonator whose cavity mode is located at $\lambda_c = 708$ nm ($P_{\text{Tot}}(\theta)$, dark and light dots, respectively) and for reference layers ($P_{\text{ref}}(\theta)$, dark and light crosses, respectively). (b) Similar plot of $P_{\text{Tot}}(\theta)$ and $P_{\text{ref}}(\theta)$ vs $\theta$ from a resonator characterized by $\lambda_c = 742$ nm. Graphs in (c) and (d) show the experimental enhancement factors ($P_{\text{Tot}}(\theta)/P_{\text{ref}}(\theta)$) for these two resonators, respectively, using the same code to identify bands. Experimental curves are multiplied by a factor 4 and 5 for the resonator of (a) and (b), respectively. Theoretical curves obtained from Eq. (3) are plotted in Figs. 3(a)–3(d) as solid lines for both resonators and as dotted lines for references. Finally, (e) and (f) show the corresponding calculated polar emission patterns of bands $\lambda_B = 708$ nm (dark lobes) and $\lambda_B = 655$ nm (light lobes) as a function of the collection angle.
center of a perfectly planar microcavity. This system was analyzed theoretically by Benisty et al.\textsuperscript{14} In that study, an expression that relates the power extracted out of the resonator, $P_{\text{out}}$, in a specific direction $\theta$ is derived

$$P_{\text{out}}(\theta) \propto \frac{2T_1}{1 - r_1 r_2 e^{2i\phi}} \frac{1 + r_2^2 - 2r_2 \cos(2\phi')}{2},$$

(1)

where $L$ is the thickness of the cavity ($L = \lambda_c/2n_c$), $k$ is the wavenumber of the emitted light inside the cavity at a wavelength $\lambda_B$ ($k = 2m_n/\lambda_B$), $r_1$ and $r_2$ are the amplitude reflectivities of the fields on the front and back mirrors, respectively, $T_1 = 1 - r_1^2$ is the front mirror transmission, $\phi' = kzc \cos z$, $z$ being the distance from the emitter to the back mirror (considered $z = L/2$), and $\phi = kL \cos z$.

Thus, the total power escaping from the resonator and collected within a cone of angular width $\theta$ is given by

$$P_{\text{TOT}}(\theta) = 2\pi \int_0^\theta P_{\text{out}}(\theta) \cdot \sin \theta \cdot d\theta.$$  

(2)

Our input parameters are the spectral position of the luminescent band, $\lambda_B$, and the finesse of the resonance, $F$, extracted from the measured spectra. The coefficients $r_1$ and $r_2$ are estimated from $F$ through the expression

$$F = \frac{\pi \sqrt{r_2}}{1 - r_1 r_2}.$$  

(3)

The calculated trends for $P_{\text{TOT}}(\theta)$ versus $\theta$, obtained from Eq. (2), are plotted as solid lines in Figs. 3(a) and 3(b) for the chosen bands, and as dashed lines for homogeneous media (reference layers). It can be seen that these are in good qualitative agreement with the experimental ones in all cases. It should be noted that, since the model does not take into account the intensities of the different emission bands of the nanophosphors of the reference, only qualitative information can be extracted from the evolution of the curve. All calculated curves shown in Figs. 3(a) and 3(b) are drawn so that the relation between the intensities of the different bands observed experimentally is preserved.

The monotonic growth of the intensity emitted at $\lambda_B = 708$ nm presents a very different angular dependence as a function of the relative position of $\lambda_c$ and $\lambda_B$. In Figs. 3(c) and 3(d), the experimental and theoretical angular dependences of the emission enhancement, estimated as the ratio between the photoluminescence power extracted at a certain collection angle $\theta$ from the resonator and that collected from the reference samples, $P_{\text{TOT}}(\theta)/P_{\text{ref}}(\theta)$, are shown. It can be seen that the theoretical trends (dark and light solid lines in Figs. 3(c) and 3(d)) are, again, in qualitative agreement with the measurements (dark and light circles in Figs. 3(c) and 3(d)).

Quantitatively, however, experimental and theoretical data differ by a factor comprised between 4 and 5. Thus, experimental curves are multiplied by a factor 4 and 5 for the resonator of Figs. 3(a) and 3(b), respectively. The differences observed are very likely due to the deviations of the experimental structure from the one considered theoretically. The main differences arise from the fluctuations of the thickness of the optical cavity as a result of the roughness introduced by the silica nanoparticles, whose average size is around 30 nm. Also, the emitters are not exactly placed in the middle of the cavity as assumed in the theoretical model, since the thickness of the layer of rare-earth based particles sandwiched between silica layers represents approximately 10% of the total thickness of the cavity. In addition, both polarization effects and the real multilayer structure of the cavity mirrors have been neglected in the model. Remarkably, in spite of all these simplifications, the model solutions nicely reproduce the main observed features. Finally, theoretical polar emission patterns are shown in Figs. 3(e) and 3(f) to further illustrate the effects herein discussed. Very different angular distribution of energy for the bands emitted at 708 nm and 655 nm are attained as a function of the resonator in which the nanophosphors are integrated. These observations are in good agreement with both experimental and theoretical studies previously realized for quantum wells enclosed by a one-dimensional photonic crystal microcavity.\textsuperscript{18}

In conclusion, the angular properties of light emitted from nanophosphors embedded in optical resonators built in one-dimensional photonic crystal coatings have been investigated. Abrupt angular variations of the enhancement caused by the photonic structure and the extraction power are observed, which are in qualitative agreement with the solutions of a simple theoretical model for light emitted by a dipole inside a perfect microcavity. Our results demonstrate that integration of nanophosphors within photonic crystals provides ways of tailoring the emission properties that could be put into practice in phosphorescent displays.
